Adenomyosis and your implications on fertility and on the results of assisted reproduction techniques (ART)

Introduction: Adenomyosis is a benign invasion of the endometrium into the myometrium, which produces an enlarged uterus with ectopic endometrial glands and stroma surrounded by the myometrium, with hyperplastic and hypertrophic changes. This condition has characteristic symptoms such as abnormal uterine bleeding, dysmenorrhea, chronic pelvic pain, miscarriage, and infertility. Objective: To assess the relationship between adenomyosis and infertility, as well as its possible impact on the outcomes of assisted reproductive technology. Methods: It is a review, with articles searched in the PubMed, UpToDate and SciELO databases, in Portuguese and English, published from 1989 to 2021. Results: Currently, the diagnosis of adenomyosis is made by imaging tests, which allow the early diagnosis in young women and makes it possible to investigate the relationship between adenomyosis and infertility. This relationship has not yet been established, but several theories have been proposed, such as impaired tubal transport, decreased sperm function related to nitric oxide levels in the uterine cavity, impaired embryo implantation, and altered uterine contractility. Furthermore, outcomes of assisted reproduction techniques and pregnancy outcomes appear to be affected, with studies showing lower rates of implantation and pregnancy, as well as higher rates of miscarriage and preterm birth. Conclusion: Although adenomyosis has negative impacts on women's fertility and on the abortion rate, more studies and research are needed to, for example, define diagnostic criteria and create protocols for approaching adenomyosis.

Keywords: Adenomyosis; Infertility; Reproduction.
Adenomyosis was defined in 1972 as a benign invasion of the endometrium into the myometrium, producing a diffusely enlarged uterus with ectopic endometrial glands and stroma surrounded by myometrium, with hyperplastic and hypertrophic alterations. It generally affects women aged 40 to 50 years, but can be found incidentally in younger women, and it may coexist with other gynecological conditions, such as endometriosis and uterine fibroids.

Although 35% of affected women are asymptomatic at the time of diagnosis, the rest may experience some symptoms such as abnormal uterine bleeding, dysmenorrhea, dyspareunia, chronic pelvic pain, miscarriages, and infertility. For many years, the diagnosis of adenomyosis was made by histopathological examination of hysterectomy. Today, with the improved resolution of transvaginal ultrasonography (TVUS) and/or magnetic resonance imaging (MRI), earlier and non-invasive diagnosis is possible with accuracy of 80% to 90%.

Diagnostic imaging has improved the understanding of adenomyosis and allowed for earlier diagnosis in younger women, making it possible to investigate the relationship between adenomyosis and infertility. This relationship, however, is not yet fully established. Several theories have been proposed, including impaired utero-tubal transport, reduced sperm function due to high levels of nitric oxide in the uterine cavity, impaired embryo implantation, altered uterine contractility, and many others. Furthermore, the outcomes of assisted reproductive techniques seem to be impaired, as well as pregnancy prognosis, with some studies demonstrating lower rates of implantation and pregnancy, and higher rates of miscarriage and preterm birth.

The purpose of this review is to evaluate the relationship between adenomyosis and infertility, and its possible...
implications on the results of assisted reproductive techniques (ART).

METHODS

This is a literature review based on articles found in the PubMed, UpToDate and SciELO databases. The descriptors used in English and Portuguese were: “adenomyosis” and “infertility”. The inclusion criteria used were to choose papers in Portuguese and English, published from 1989 to 2021, including literature reviews, clinical protocols, books and original articles, full text available. Duplicate studies, abstracts, and those in the approval process were excluded. The results were presented descriptively (Table 1), divided into categories that included: introduction, correlation between adenomyosis and infertility, impact of adenomyosis over reproductive outcomes, and adenomyosis treatments.

RESULTS

CORRELATION BETWEEN ADENOMYOSIS AND INFERTILITY

Until recently, the diagnosis of adenomyosis was most often made by an anatomical and pathological study based on hysterectomies. The pathology was then related to multiparous women, and not to infertility. With recent advances in imaging techniques, the diagnosis has now been made by transvaginal ultrasound and MRI, which has made it possible to see the women conditions other than just multiparous women, including nulliparous and infertile women, allowing the relationship between adenomyosis and infertility to be observed and studied6.

One third of women with adenomyosis are infertile (Bourdon et al., 2020). A systematic review showed a 28% decline in pregnancy rate in patients with adenomyosis submitted to IVF, and an increase in miscarriage rate1.

There are several mechanisms proposed to link adenomyosis and infertility. Among them are the anatomical distortions caused themselves by the disease, such as the overall increase in uterine volume, the presence of intramural adenomyomas that distort the endometrial cavity; abnormal uterine contractility; changes in endometrial vascularization and histology; inflammatory, molecular, and hormonal endometrial alterations7.

The presence of myometrial contraction waves is physiological and visible on the ultrasound. This peristaltic activity is what helps out with the transport of sperm towards the fallopian tubes, which is fundamental in the initial reproductive process, and it depends on the architecture of the myometrial wall and its circular muscle fibers8. In adenomyosis patients, the invagination of endometrial glands and stroma in the myometrium leads to hyperplasia of the muscle tissue culminating in peristaltic dysfunction and increased intrauterine pressure. Also, the junctional zone (JZ) - a layer of myometrium that is adjacent to the endometrium - in women with adenomyosis shows nuclear and cellular hypertrophy, mitochondrial changes and other ultrastructural alterations that may lead to calcium channel dysfunction with subsequent loss of rhythmic contraction and that may alter uterine-tubal transport4.

During the peri-implantation period, the myometrial activity must be kept at a minimum level to facilitate the apposition, adhesion, and penetration of the embryonic pole of blastocyst into the decidualized endometrium7. Research focusing on myometrial contraction patterns during the embryo transfer has demonstrated lower pregnancy and implantation rates in patients who show a higher frequency of uterine junctional zone activity9.

The currently most accepted theory to explain the histological phenomena is that basal endometrial glands invade the underlying myometrium, causing intrinsic adenomyosis, affecting the JZ as well as the myometrium10. Piver proposed that MRI evaluation of JZ thickness is the best predictive negative factor of implantation failure, and an increase in its diameter is inversely related to the implantation rate. It was seen that implantation failure was elevated when the JZ average was higher than 7 mm. Also, the endometrial receptivity seems to be compromised due to the extremely increased vascularity in the secretory phase, which may negatively affect the implantation rates11.

Some ultrasonographic criteria regarding patients with adenomyosis showed a negative correlation between results of assisted reproduction treatments12. It was attributed a lower success rate after the IVF, the higher the number of criteria identified in the patient. The criteria described were: asymmetry of myometrial wall thickness (A), parallel shadows (B), linear striations (C), myometrial cysts (D), hyperechogenic islands (E), adenomyomas (F), and irregular myometrial endometrial junction (G) (Figure 1).

A study on the molecular phenomena demonstrated a decreased endometrial receptivity and an impaired decidualization in adenomyosis associated with alterations in gene expression of HOXA10 (a necessary component of endometrial receptivity with a spike in the implantation window), in LIF (leukemia inhibitory factor), MMP (metalloproteinases), interleukins (IL-6, IL-8 and IL-10), among others13. Meanwhile found a correlation between down regulation of FOXO1A in adenomyotic tissue and inadequate decidualization, which could compromise the embryo implantation in patients with adenomyosis14. However, there is still not enough research to prove whether these changes can be restored with the use of progesterone during the implantation window15.

The abnormal inflammatory response has been much studied. Macrophages can produce not only pro-inflammatory cytokines such as TNF-α (tumor necrosis factor alpha) and IL-1, but also free radicals that can be toxic to embryos16. Noticed that women with severe adenomyosis, who had embryo implantation failure, showed an increase in macrophage density compared to control patients. In the case of adenomyosis, there is also an increased expression of IL-1b and CRH (corticotropin-releasing hormone) in the ectopic endometrial tissue17. Reported an increased in inflammatory response in the

<td>2013</td>
<td>Retrospective study</td>
<td>339 patients with adenomyosis were included in the study. Of these, 194 received GnRH agonist plus HRT (hormone replacement therapy) and 145 received HRT alone. There were no differences between groups in characteristics such as age, body mass index, duration or cause of infertility, serum CA-125 level and baseline hormone levels. On the day of progesterone administration, mean endometrial thickness and serum progesterone level were significantly higher in HRT patients. In the aGnRH + HRT group, the rates of clinical pregnancy, implantation, and ongoing pregnancy were 51.35%, 32.56%, and 48.91%, respectively, significantly higher than those in the HRT group (24.83%, 16.07% and 21.38%, respectively). Thus, it was concluded that GnRH agonist pretreatment significantly improved pregnancy outcomes in patients with adenomyosis.</td>

<tr>
<td>Bourdon et al. 21</td>
<td>2020</td>
<td>Observational study</td>
<td>A total of 496 women were included in the study population. Three groups were compared: a group without infertility ($n = 361$), a group with primary infertility ($n = 84$), and a group with secondary infertility ($n = 51$). Among them, 248 women did not have adenomyosis lesions and 248 women had a radiological diagnosis of adenomyosis. The presence of FAOM (focal adenomyosis of the external myometrium) was significantly associated with primary infertility. Diffuse adenomyosis has not been associated with infertility. The distribution of endometriosis or leiomyomas was not significantly different between groups. After a multinomial regression model including women’s age and associated endometriosis or leiomyoma, the presence of FAOM was identified as an independent associated factor of primary infertility (adjusted odds ratio 1.9; 95% confidence interval 1.1-3.3).</td>
</tr>
<tr>
<td>Piver 10</td>
<td>2005</td>
<td>Cohort Study</td>
<td>Women with adenomyosis who became pregnant in IVF cycles had a mean junctional zone (AJZ) value of 5.1mm compared to 6.3mm in non-pregnant women ($p &lt; 0.0001$). Similarly, pregnant women had a significantly lower maximum junctional zone (MJZ) value than non-pregnant women (6.2 mm versus 9.8 mm, $p &lt; 0.0001$). For patients with MJZ less than 10 mm, pregnancy rates were 45% per transfer. For those with an MJZ between 10 and 12 mm, the transfer pregnancy rate was 16%. Finally, for women with an MJZ greater than 12 mm, the transfer pregnancy rate was 5%. This influence of junctional zone thickness was independent of age. After logistic regression, it was found that the association of AJZ &gt; 7 mm and MJZ &gt; 10 mm is a risk factor for IVF failure (absence of pregnancy). This relationship is highly significant ($p = 0.0007$) with an OR of 32 and a confidence interval between 4.2 and 241, meaning that abnormal thickness of the junctional zone is recognized as a cause of pregnancy failure in IVF, and much more than a simple risk factor.</td>
</tr>
<tr>
<td>Vercellini et al. 4</td>
<td>2014</td>
<td>Systematic review and meta-analysis</td>
<td>In the five selected observational studies, in women seeking pregnancy, 11.9% women with concomitant adenomyosis became pregnant, compared with 74/172 (43.0%) in those without adenomyosis. One in 10 women undergoing surgery for rectovaginal and colorectal endometriosis had a serious surgical complication. The RR of clinical pregnancy consistently ranged from 0.23 to 0.46 after surgical resection. Adenomyosis was associated with a 68% reduction in the likelihood of pregnancy in women trying to conceive after surgery for rectovaginal and colorectal endometriosis.</td>

<tr>
<td>Mijatovic et al.25</td>
<td>2010</td>
<td>Retrospective cohort study</td>
<td>Study evaluated 74 women who underwent IVF/ICSI. Adenomyosis was demonstrated in 27% of them and was predominantly located on the posterior wall of the uterus. No significant differences were found for any of the IVF/ICSI outcomes (number of embryos, fertilization rate, implantation rate, clinical pregnancy rate, and miscarriage rate) between women with and without adenomyosis.</td>
</tr>
<tr>
<td>Thalluri et al.26</td>
<td>2012</td>
<td>Retrospective cohort study</td>
<td>The presence of adenomyosis diagnosed by ultrasound was associated with a significant reduction in the successful implantation of good quality embryos in patients undergoing GnRH antagonist stimulation for IVF treatment (clinically viable pregnancy rate 23.6% versus 44.6%, P = 0.017). However, the median maternal age and duration of infertility of the adenomyosis group were 2 years older and 4 months higher, respectively, than those of the non-adenomyosis group. A logistic regression analysis was performed to explain these differences between the two groups, with the adjusted results still showing a statistically significant decline in the viable pregnancy rate in the adenomyosis group (OR = 0.408, CI = 0.181-0.922, P = 0.031 when adjusted for maternal age; OR = 0.417, CI = 0.175-0.989, P = 0.047 when adjusted for duration of infertility). The results of this study should be representative of the results of any patient undergoing a cycle of GnRH antagonist ovarian stimulation for IVF, as standard IVF treatment protocols were used.</td>
</tr>
<tr>
<td>Martínez-Conejero et al.27</td>
<td>2011</td>
<td>Retrospective cohort study</td>
<td>Endometrial samples were analyzed using microarrays in women with adenomyosis and healthy controls. The clinical study included three groups: adenomyosis, endometriosis and control. There is a similar endometrial gene expression pattern in both the adenomyosis group and the control group, and non-parametric tests revealed 34 dysregulated genes in adenomyosis patients, but none belonged to the implantation window gene group. Egg donation implantation did not differ between the three groups. However, miscarriage was significantly higher in the adenomyosis group versus the adenomyosis + endometriosis and control groups. The full-term pregnancy rate was also significantly lower in the adenomyosis group compared to others.</td>
</tr>
</tbody>
</table>

endometrium due to the presence of an elevated level of the expression of pro-oxidatives and anti-oxidatives such as Cu, Zn-SOD and Mn-SOD. Other studies confirmed these data by investigating the concentration of nitric oxide in the endometrium, macrophage activity, and IL-6. An increased expression of cytochrome P450 aromatase (P450 aromatase) in the endometrium has also been suggested as a possible mechanism that negatively affects implantation in women with adenomyosis. The aromatase of the P450 chromosome is an enzyme that catalyzes the conversion of androgens to estrogens. The hyperestrogenic microenvironment maintains the expression of the α estrogen receptor increased during the secretory phase that should normally have decreased under the effect of progesterone. Early publications confirmed higher estrogen levels in menstrual blood in adenomyotic women and an increase in aromatase expression of cytochrome P450 in the endometrium, respectively.
Integrins are the best known and well-studied markers of endometrial receptivity. They are transmembrane receptors that, besides being responsible for endometrial receptivity, activate signaling pathways and mediate cell signaling, such as cell cycle regulation. Abnormal expressions of some integrins, such as $\beta$-3 and osteopontin (OPN) were found in patients with adenomyosis, and it was suggested that this expression was responsible for IVF failures, even with good quality embryos. The influence of GnRH analogues on integrin expression and endometrial receptivity have already been described in animals but cannot be conclusive in human pathology\textsuperscript{15}.

There are still many questions about the relationship of adenomyosis with infertility. This is mainly due to the different classifications of the disease, as well as the mixed profiles of patients (focal and diffuse adenomyosis), which makes more precise conclusions difficult. In all women affected by adenomyosis (focal, diffuse or an association of the two types) the prevalence of infertility is 30.2\%, 19.8\% being primary infertility and 10.5\% secondary\textsuperscript{21}.

Therefore, from the studies cited above and many others existing in the literature on the subject, it is possible to affirm that there is probably a relationship between adenomyosis and infertility. This relationship is due to molecular and histological phenomena, which are not yet fully understood, being necessary that more studies that are methodologically adequate can be carried out. The elucidation of the relationship between adenomyosis and infertility will provide a better understanding of the lower pregnancy rates in patients of adenomyosis, including those submitted to assisted reproduction treatments, besides the development of possible therapeutic interventions and strategies during the treatments seeking improvement in the results.

**Impact of Adenomyosis on Reproductive Outcomes**

Recent studies have shown that adenomyosis negatively affects fertility, besides increasing the risk of obstetric complications, such as miscarriage, preterm delivery, and the premature rupture of amniotic membranes\textsuperscript{22}. However, there are still few studies evaluating the impact of adenomyosis on reproductive outcomes of assisted reproductive techniques, such as implantation rate, pregnancy rate, and live birth rate\textsuperscript{23}.

Younes and Tulandi (2017)\textsuperscript{2} demonstrated in their meta-analysis, which evaluated 15 studies, that women with adenomyosis had a worse outcome in IVF cycles. Patients with adenomyosis who were submitted to IVF had significantly lower implantation, clinical pregnancy,
Adenomyosis and Infertility

The odds ratio for clinical pregnancy rate when comparing women with adenomyosis and women without adenomyosis submitted to IVF was 0.73, 95%CI=0.60-0.90. Meta-analysis demonstrated that the presence of adenomyosis was associated with a 41% reduction in live birth rate (OR=0.59, 95%CI=0.42-0.82). Furthermore, the group of women with adenomyosis had a significantly higher miscarriage rate (OR=2.2, 95%CI=1.53-3.15). These data are in line with a previous systematic review and meta-analysis that showed a clinical pregnancy rate of 40.5% for women with adenomyosis submitted to IVF compared to 49.8% in women without adenomyosis (RR=0.72, 95%CI=0.55-0.95).

Chiang et al. (1999) studied the relationship of miscarriage rate and JZ dysfunction in infertile patients submitted to IVF and concluded that the rate was higher in women with a diffusely enlarged uterus on ultrasound without distinct uterine masses compared to those with a normal sized uterus. In contrast, Mijatovic et al. (2010) observed no significant differences in pregnancy rates in infertile patients with adenomyosis in association with endometriosis who were pretreated with long-acting GnRH agonist. Furthermore, Thalluri e Tremellen (2012) noticed significantly lower clinical pregnancy rates in patients submitted to IVF with adenomyosis in cycles that used the antagonist protocol of GnRH when compared to patients without adenomyosis (23.6% vs. 44.6%, p=0.017).

In a study evaluating ooverecpception cycle, it was observed that women with adenomyosis had double the risk of miscarriage when compared to the group of women without adenomyosis, indicating an impact on pregnancy outcome.

TREATMENTS FOR ADENOMYOSIS

The treatment of adenomyosis is still discussed and questioned by several experts, and the clinical treatment and surgical approach are among the methods of choice for possible therapy of this pathology. The decision between clinical or surgical approach will depend on the symptoms presented by the patient and the desire or not for pregnancy.

Drug treatment for adenomyosis can be used for the relief of symptoms such as dysmenorrhea and abnormal uterine bleeding. Among the clinical approach, we have non-steroidal anti-inflammatory drugs (NSAIDs), oral hormonal contraceptives, progestins, progestrone-releasing intrauterine devices, and gonadotropin-releasing hormone agonist. On the other hand, the definitive treatment for adenomyosis is hysterectomy. However, for patients who desire pregnancy, drug treatment or hysterectomy cannot be adopted.

Oral hormonal contraceptives are a great option for reducing abnormal uterine bleeding, as well as reducing dysmenorrhea by inducing decidualization, which may result in amenorrhea due to endometrial atrophy. However, there are still few studies evaluating the impact of oral hormonal contraceptive use in patients with adenomyosis and its relationship to the future fertility of these patients.

Another drug treatment option used is gonadotropin-releasing hormone agonist (GnRHa). This drug’s main action is to reduce adenomyosis macroscopically and microscopically and decrease clinical effects, such as normal bleeding, pain, and infertility. GnRHa has an antiproliferative effect on endometrial tissue, induces apoptosis, and reduces inflammatory reaction and angiogenesis, helping in the regression of the disease. Importantly, this strategy has resulted in some case reports of successful pregnancy and delivery in women submitted to this treatment. A disadvantage of using this medication is that it has a transient effect, therefore, it is priced to be used as a preoperative adjunctive therapy in surgical treatment. In their meta-analysis, Yones et Tulandi (2017) concludes that the use of GnRHa prior to IVF appears to be beneficial for the pregnancy rate in women with adenomyosis. However, this result was based on only two studies. As such, more studies become necessary to confirm this potentially beneficial effect of using GnRHa prior to the IVF cycle.

The levonorgestrel intrauterine device (IUD) has been emerging as a new option for the conservative treatment of adenomyosis. Randomized studies that evaluated the use of the device in women with adenomyosis associated with menorrhagia have demonstrated a significant reduction in both uterine volume and average thickness of the JZ. Its clinical effects show satisfactory results in the control of dysmenorrhea and menorrhagia symptoms, as well as reports of spontaneous pregnancy after its use.

The dienogest (DNG), which is a 19-norsteroid progesterational derivative, is a synthetic oral progestin with highly selective attachment to progesterone receptors, has been pointed out as a new therapeutic alternative for the subgroup of patients with adenomyosis and pelvic pain. This drug has mild anovulatory and hypoestrogenic effects, and antiproliferative activity in human endometrial cells. Based on this hormonal profile, DNG is used as a treatment for pain symptoms in patients with endometriosis. Therefore, some studies have shown an efficacy and good tolerability of DNG in patients with adenomyosis and an algie complaints.

Surgical treatment can be divided into a conservative approach reserved for focal adenomyosis or adenomyoma or hysterectomy. However, for obvious reasons hysterectomy is not a therapeutic option for infertile patients or those who wish to preserve their fertility. For this patient profile, conservative surgery may be a therapeutic option. However, the data available in the literature are still controversial and insufficient, mainly because most of the published studies were not designed for this purpose.

Surgical excision (laparoscopic or laparotomy) of adenomyoma or focal adenomyosis aims to preserve the uterus in order to preserve the future fertility of the patient, as well as significant improvement of dysmenorrhea.
However there are some drawbacks in the choice of surgery, such as: difficulty in selecting a good candidate to submit to this surgical approach (problem to determine the extent of adenomyosis in a given patient), possible failure to completely eliminate adenomyosis and postoperative sequelae, such as pelvic adhesions, syncytial formation in the endometrial cavity, increased risk of uterine rupture during labor, increased risk of miscarriage, premature delivery, and placental complications such as accretism\textsuperscript{28,34}.

On the other hand, surgery for myometrial reduction, which consists of the surgical removal of the affected myometrial tissues, is an alternative treatment option. This is a complex surgical procedure involving the removal of adenomyotic tissues, which is associated with an increased risk of intraoperative bleeding, as well as an increased chance of uterine rupture during subsequent pregnancy and intrauterine synctity. There are no controlled studies evaluating the effect of this surgery on fertility, and it should therefore not be an approach for patients seeking fertility preservation\textsuperscript{29}.

Uterine artery embolization may be able to produce changes in the areas of adenomyosis with decreased vascularization of the JZ; however, this type of treatment is not indicated for infertile patients due to the risk of inducing premature ovarian failure, besides being able to interfere with endometrial receptivity\textsuperscript{32}.

The focal therapy with high-intensity focused ultrasound (HIFU) uses the thermal effect of the ultrasound beam, which causes coagulative necrosis within the target adenomyotic lesion. Thus, this method would be indicated for focal adenomyosis, being inadequate for the diffuse form. The advantage of this method would be a faster recovery time when compared to classical surgical techniques\textsuperscript{35}.

**Conclusion**

Adenomyosis has a negative impact on fertility with reduced pregnancy rate and increased abortion rate. The treatment of infertility associated with adenomyosis is still a very complex issue that needs more scientific support to define the best management and approach. So far there is no scientific evidence to indicate any surgical treatment for women with adenomyosis and desire for pregnancy or that are in infertility treatment. Surgery for adenomyosis, whether conservative or radical, is reserved for cases of symptomatic women (dysmenorrhea and abnormal uterine bleeding) with defined progeny.

Based on current data, the recommendations for the definition of the best treatment for adenomyosis in infertile women are based on weak evidence, and assisted reproductive techniques are an available resource in these cases. The literature shows us that the use of GnRh agonist before the IVF cycle can be beneficial, improving reproductive outcomes. However, further studies are still needed to answer the still existing doubts, define diagnostic criteria, and create protocols to approach adenomyosis.

**Author’s Contribution**

AM Miranda proposed the theme developed and participated in the review and guidance. MC Magalhaes participated in the review and guidance. LB Viana participated in the bibliographic survey and the results of the article, carried out the introduction and conclusion of the article and sent the article. LB Lima participated in the results of the article and the bibliographic survey. SO Domingos carried out the production of references and methodology, and participated in the bibliographical survey and the production of the result of the article. LM Amaral produced the abstract of the article in question, as well as participated in the bibliographic survey and the production of the article’s result. All authors conceptualized, discussed, read and approved the final version of the article.
